Abstract: The aim of this study is to evaluate the effect of dexmedetomidine on erythrocyte deformability during IR heart injury in diabetic rats.

Methods: Eighteen Wistar Albino rats were included in the study after streptozocin (55 mg/kg) treatment for four weeks. In the Group C and DC (sham-control group), the coronary artery was not occluded or reperfused in the control rats. In the Group DIR, a branch of the left coronary artery was occluded for 30 minutes followed by two hours of reperfusion to produce IR. In the Group DIRD, a branch of the left coronary artery was occluded for 30 minutes followed by two hours of reperfusion to produce IR, and dexmedetomidine was administrated via 100 μg/kg IP route 30 minutes before ligating the left coronary artery. Deformability measurements were performed in erythrocyte suspensions containing Htc 5 % in a PBS buffer.

Results: The deformability index was significantly increased in diabetic rats; however, it was similar in the Group DC and DIRD. It was significantly increased in the Group DIR when compared to the Group C, DIRD and DC.

Conclusion: Erythrocyte deformability was decreased in rats having diabetes and IR injury. This injury might lead to further problems in microcirculation. It was shown that dexmedetomidine might be useful in enhancing the adverse effects of this type of injury (Fig. 1, Ref. 39). Text in PDF www.els.sk

Key words: erythrocyte deformability, myocardial ischemia reperfusion, experimental diabetes, dexmedetomidine, rat.

In last two or three decades, the prevalence of diabetes mellitus (DM) has rapidly increased throughout the world, and experts estimate that it will increase by 200 % in the next several decades (1–4). Diabetes mellitus affects patients of all ages and, due to its increasing prevalence, most physicians will be confronted with diabetic patients requiring anaesthesia and surgery. Patients with diabetes have a significantly increased risk of premature mortality and an increased risk of microvascular and cardiovascular complications. These patients are often sicker than most non-diabetic patients; therefore, they place a proportionally larger burden on anaesthetic services (2, 5, 6). Thus, more careful perioperative care is necessary for these patients (7).

A 50 % increase in early mortality following coronary artery bypass grafting has been described in diabetic patients (5). One study demonstrated that the rate of unrecognised myocardial infarction was 39 % in diabetic patients and 22 % in non-diabetic patients (8). Cardiac surgery with cardiopulmonary bypass inevitably causes a systemic inflammatory response and ischaemia–reperfusion (IR) injury affecting multiple organs (1, 2).

Many tissues and cells can be damaged by free radicals, with red blood cells (RBC) being one of the most susceptible. During IR, the increased oxidative stress (OS) can cause augmented RBC membrane lipid peroxidation with the consequent alteration of cellular deformability. Erythrocyte deformability is of crucial importance for the maintenance of normal circulation, as it facilitates the passage of RBC through narrow capillaries in the microcirculation and reduces blood viscosity at high shear rates in large blood vessels (9).

Haemorheological parameters that include (but are not limited to) hematocrit, plasma proteins, erythrocyte aggregation and erythrocyte deformability in DM are often disturbed (10).

Several drugs in anaesthesia have been used to prevent IR injury, including sevoflurane, dexmedetomidine, isoflurane and ketamine (11–15). Dexmedetomidine, a selective and potent α2-adrenoceptor agonist, was approved by the US Food and Drug Administration (FDA) in 1999 for the sedation of patients hospitalized in intensive care settings. Since then, a growing number of research articles have emerged reporting other possible indications, such as regional and general anaesthesia (16, 17). Dexmedetomidine was reported to be effective in protecting against focal ischaemia in rabbits, in cardiac IR injury in rats, in kidney IR injury in rats and in incomplete forebrain ischaemia in rats (12, 18–20). Despite its increased clinical use in critically ill patients, the effects of dexmedetomidine on ischaemic injury induced by left coronary artery (LAD) IR have not yet been investigated.

The primary aim of this study was to investigate deformability changes and the preventive role of dexmedetomidine against these
changes in erythrocytes of diabetic rats during an experimental model of myocardial IR injury.

**Materials and methods**

**Animals and Experimental Protocol**

This study was conducted in the GUDAM Laboratory of Gazi University with the consent of the Experimental Animals Ethics Committee of Gazi University. All of the procedures were performed according to the accepted standards of the Guide for the Care and Use of Laboratory Animals.

In the study, 24 male Wistar Albino rats weighing between 200 and 250 g, raised under the same environmental conditions, were used. The rats were kept at 20–21 °C in cycles of 12 hours of daylight and 12 hours of darkness and had free access to food until two hours before the anaesthetic procedure. The animals were randomly separated into the four groups, each containing six rats.

Diabetes was induced by a single IP injection of streptozotocin (Sigma Chemical, St. Louis, MO, USA), at a dose of 55 mg·kg⁻¹ body weight. The blood glucose levels were measured 72 hours following this injection. Rats were classified as diabetic if their fasting blood glucose (FBG) levels exceeded 250 mg·dl⁻¹, and only animals with FBGs of > 250 mg·dl⁻¹ were included in the diabetic groups (diabetes only, diabetes plus ischaemia–reperfusion and diabetes plus dexmedetomidine–ischaemia–reperfusion). The rats were kept alive for four weeks after streptozotocin injection to allow the development of chronic diabetes before they were exposed to ischaemia–reperfusion (21). The rats were weighed before the study.

Rats were anesthetized with an IP injection of 100 mg·kg⁻¹ of ketamine. The trachea was cannulated for artificial respiration. The chest was shaved and each animal was fixed in a supine position on the operating table. The chest was opened by a left thoracotomy followed by sectioning the fourth and fifth ribs about 2 mm to the left of the sternum. Positive-pressure artificial respiration was started immediately with room air, using a volume of 1.5 ml/100 g body weight at a rate of 60 strokes/min. Sodium heparin (500 IU/kg) was administered through the peripheral vein in the tail.

After the pericardium was incised, the heart was exteriorized with gentle pressure on the right side of the rib cage. An 8/0 silk suture attached to a 10-mm micropoint reverse-cutting needle was quickly placed under the left main coronary artery. The heart was then carefully replaced in the chest and the animal was allowed to recover for 20 minutes.

There were four experimental groups. The Group C (control; n = 6), Group DC (diabetes-control; n = 6), Group DIR (diabetes–ischaemia–reperfusion; n = 6) and Group DIRD (diabetes–ischaemia–reperfusion–dexmedetomidine; n = 6) underwent left thoracotomy and received IP dexmedetomidine (Precedex 100 μg/2 ml, Abbott®, Abbott Laboratory, North Chicago, IL, USA) administrated via 100 mg·kg⁻¹ IP route 30 minutes before ligating the LAD (13). A small plastic snare was threaded through the ligature and placed in contact with the heart. The artery could then be occluded by applying tension to the ligature (30 minutes), and reperfusion was achieved by releasing the tension (120 minutes) (12). However, after the above procedure, the coronary artery was not occluded or reperfused in the control and diabetic control rats.

All the rats were given ketamine 100 mg·kg⁻¹ IP and intracardiac blood samples were obtained. Heparinized total blood samples were used to prepare erythrocyte packs. Deformability measurements were performed using erythrocyte suspensions with 5 % haematocrit in a phosphate buffered saline (PBS) buffer.

**Deformability measurements**

Blood samples were carefully taken and the measurement process was as fast as possible to avoid haemolysis of erythrocytes. The collected blood was centrifuged at 1000 rpm for ten minutes. Serum and buffy coat on erythrocytes were removed. An isotonic PBS buffer was added to the collapsing erythrocytes and this was centrifuged at 1000 rpm for ten minutes. Liquid on the upper surface was removed. Finally, pure red cell packs were obtained from the washing process, which was repeated three times. Erythrocyte packs were mixed with the PBS buffer to generate a suspension with a value of 5 % Htc. These erythrocyte suspensions were used for the measurement of deformability. Collection and deformability measurements of erythrocytes were performed at 22 °C.

The constant-current filtrometer system was used in the measurement of erythrocyte deformability. Samples to be measured were prepared with 10 ml of erythrocyte suspension and PBS buffer. The flow rate was held constant at 1.5 ml/min with an infusion pump. A 28 mm nucleoporin polycarbonate filter with a 5 μm pore diameter was preferred. Pressure changes while the erythrocytes passed through the filter were detected by the pressure transducer, and the data was transferred to the computer with the help of an MP30 data equation system (Biopac Systems Inc, Commat, USA). The necessary calculations were performed with related computer programs by measuring the pressure changes at various times. Pressure calibration of the system was performed before each sample measurement. The buffer (P₀) and the erythrocytes (Pₑ) were passed through the filtration system and the changes in pressure were measured. The relative refractory period value (Rrel) was calculated by relating the pressure value of the erythrocyte suspension to the pressure value of buffer. Increasing
Rrel in the deformability index was interpreted to adversely affect the erythrocytes’ deformability (22, 23).

**Statistical analysis**

The Statistical Package for the Social Sciences (SPSS, Chicago, IL, USA) 12.0 program was used for the statistical analysis. Variations in blood glucose levels, erythrocyte deformability and rat weights between study groups were assessed using the Kruskal–Wallis test. The Bonferroni-adjusted Mann–Whitney U test was used after significant Kruskal–Wallis to determine which groups differed from the others. Results were expressed as the mean ± standard deviation (Mean ± SD). Statistical significance was set at the p value of < 0.05 for all analysis and p < 0.033 (0.1/3) for Bonferroni-adjusted Mann-Whitney U.

**Results**

Blood glucose measurements were 85.8 ± 10.4, 335.4 ± 50.5, 343.7 ± 66.3 and 338.3 ± 55.8 mg/dL for Group C, DC, DIR and DIRD, respectively. Serum glucose was detected to be significantly lower in the Group C when compared to the Groups DC, DIR and DIRD (p < 0.0001).

The deformability index was significantly increased in the diabetic rats (p < 0.0001); however, it was similar in the Group DC and DIRD (p = 0.912). It was significantly increased in the Group DIR when compared to the Group C, DC and DIRD (p < 0.0001, p < 0.0001, p = 0.011, respectively) (Fig. 1). Relative resistance was increased in IR models.

**Discussion**

Diabetes mellitus (DM) is a metabolic disorder characterized by abnormally high blood sugar (hyperglycaemia) resulting from either low insulin levels or insulin resistance in most of the body cells. Diabetes mellitus has a high social and economic importance, as the number of diabetes patients continues to grow at an unprecedented rate throughout the world (10).

Haemorheological parameters, such as haemocrit, plasma proteins, erythrocyte aggregation and erythrocyte deformability are often disturbed in DM (24). For migration of oxygen and vital molecules to the final organ capillaries and clearance of metabolic wastes, erythrocytes must be able to extend and curve and have the capability to move in these areas. This capacity, called “deformability”, becomes more important in microcirculation. Altered erythrocyte deformability not only changes the oxygen delivery capacity of the erythrocytes but also the survival of the circulating erythrocytes (25–27).

Additionally, it has been suggested that the impaired perfusion at the tissue level observed as a complication of DM is primarily due to reduced erythrocyte deformability (28, 29). In addition, metabolic changes and tissue perfusion due to cardiovascular problems may lead to an inadequate recovery in plasma viscosity (30).

Cho et al (10) demonstrated that blood viscosity significantly increased in diabetes. These results suggest that the consequent elevation of glucose in blood plasma primarily affects RBCs and the vascular endothelial cells, including the walls of capillaries. The impaired glucose tolerance or uncontrolled blood glucose levels often result in microvascular complications in diabetes. Moreover, the impairment of erythrocyte deformability is attributed to the specific changes in the membrane structure. The oxidative stress due to high glucose concentrations causes damage to the erythrocyte membrane proteins, even with a relatively short exposure time (31).

Barnes et al (32) showed that erythrocyte deformability was lower in 14 diabetes patients with the most extensive micro-angiopathy than in the controls or 22 diabetes patients with slight or no complications. They suggested that hyperviscosity and reduced erythrocyte deformability may be important and potentially treatable factors in the aetiology or progression of microcirculatory disease in diabetes. Similar to these previous studies, we also found that erythrocyte deformability was decreased in rats with induced diabetes.

In this study, for the first time to our knowledge, we reported that IR of the diabetic rat heart resulted in significant negative changes that can be observed in erythrocyte deformability and that dexmedetomidine, a highly potent and selective α2-adrenoceptor agonist, administered at the beginning of heart ischaemia, can provide varying degrees of protection against negative effects of variations in erythrocyte deformability.

Dexmedetomidine is a highly selective alpha-2 agonist that provides sedation and analgesia without respiratory depression. It activates pro-survival kinases and attenuates ischaemia and hypoxic injury, including cardioprotection (33), neuroprotection (34) and renoprotection (35). Concurrent infusion during surgery reduces anaesthetic consumption by 20–50% (36) and produces a moderate decrease in heart rate and blood pressure that may be advantageous in ischaemic heart disease by improving the balance of oxygen supply and demand (37).

In a study regarding α2 agonists, Belhoula et al (38) reported that premedication of type-2 diabetic patients with clonidine 90 minutes before surgery improved blood glucose control and decreased insulin requirements during ophthalmic surgery. The clonidine decreased circulating catecholamines despite having no effect on cortisol concentrations and GH secretion. However, Venn et al (39) reported that dexmedetomidine decreased insulin secretion after major surgery without exacerbating the glycaemic response. This report suggested that an impaired insulin secretion was balanced by reduced sympathetic activity. At present, it would be reasonable to accept that α2 agonists, such as clonidine or dexmedetomidine, modify insulin secretion without exacerbating the glycaemic response.

In conclusion, the results of this study clearly demonstrated that erythrocyte deformability is significantly altered in the experimental myocardial IR injury in the diabetic rat. This might lead to further problems in microcirculation. Thus, measurement of erythrocyte deformability might have an important impact on the follow-up for IR injury. Additionally, dexmedetomidine administered before induction of ischaemia was observed to have protective effects on these alterations in myocardial IR injury. Other aspects of these findings, including clinical significance and practical applications, merit further experimental and clinical investigation.
